Abstract

An analytic calculation of the differential cross section for elastic Compton scattering on the deuteron at photon energies ω in the range of $25 - 50$ MeV is presented to next-to-next-to-leading order, i.e. to an accuracy of $\sim 3\%$. The calculation is model-independent and performed in the low energy nuclear Effective Field Theory without dynamical pions. The iso-scalar, scalar electric and magnetic nucleon polarisabilities α_0 and β_0 enter as free parameters with a theoretical uncertainty of about 20%. Using data at $\omega_{\rm Lab} = 49$ MeV we find $\alpha_0 = 8.4 \pm 3.0(\text{exp}) \pm 1.7(\text{theor})$, $\beta_0 = 8.9 \pm 3.9(\text{exp}) \pm 1.8(\text{theor})$, each in units of 10^{-4} fm^3. With the experimental constraint for the iso-scalar Baldin sum rule, $\alpha_0 = 7.2 \pm 2.1(\text{exp}) \pm 1.6(\text{theor})$, $\beta_0 = 6.9 \mp 2.1(\text{exp}) \mp 1.6(\text{theor})$. A more accurate result can be achieved by: (i) better experimental data, and (ii) a higher order theoretical calculation including contributions from a couple of so far undetermined four-nucleon-two-photon operators.

Albeit scalar electric and magnetic polarisabilities are fundamental properties of the neutron, there is a fair amount of uncertainty in their values for the lack of free neutron targets. Thus, one has to resort to indirect methods to extract neutron polarisabilities. For example, Rose et. al. depend on a particular treatment of the neutron as a quasi-free particle inside the deuteron and find for inelastic Compton scattering on the deuteron $\gamma d \to \gamma np$ that[1] $\alpha^{(n)} = 10.7^{+3.3}_{-10.7}$ [1]. Since the strong electromagnetic field of a heavy nucleus could enhance small effects from polarisability contributions, neutron scattering off a heavy nucleus is another method employed. However, analyses of low energy neutron-lead scattering experiments give conflicting values: $\alpha^{(n)} = 12.3 \pm 1.5 \pm 2.0$, $\beta^{(n)} = 3.1 \mp 1.5 \mp 2.0$ in Ref. [2], and more recently as part of an investigation of additional nuclei $\alpha^{(n)} = 0 \pm 5$ in Ref. [3]. In contradistinction, the scalar proton polarisabilities are well-measured from Compton scattering off the proton [4]: $\alpha^{(p)} = 12.1 \pm 0.8 \pm 0.5$ and $\beta^{(p)} = 2.1 \mp 0.8 \mp 0.5$, respectively.

On the theoretical side, a self-consistent and controlled description of the polarisabilities is only encountered with the dawn of Chiral Perturbation Theory (χPT) [5]. Unfortunately, estimates of corrections beyond leading order (LO) in χPT are difficult due to unknown parameters which already enter at next-to-leading order (NLO) [6, 7]. In this paper, we propose low energy Compton deuteron scattering as a probe for neutron polarisabilities. This is not a new idea and has fervently been advocated by Levchuk and L'vov, by Weyrauch, and by Arenhövel, Wilhelm and Wilbois, most recently in Refs. [8, 9, 10]; for its history see Ref. [11] and references therein. That the χPT values for the iso-scalar polarisabilities are consistent with Compton scattering data on the deuteron was demonstrated in two Effective Field Theory (EFT) NLO calculations in extensions of χPT to the few nucleon system, one using perturbative pions [12], one using non-perturbative pions [13].

The present calculation is unique in the sense that all the theoretical approximations are explicit and controlled, up to the order of the perturbative EFT calculation. The polarisabilities extracted from this calculation are independent of any modelling of the short-distance dynamics of nucleons inside a deuteron or any heavy nucleus. In particular, they are independent of assumptions about the pion-nucleon interaction, independent of the form of the inter-nucleon potential, manifestly independent of the photon coupling to nucleons and pions as extended objects and independent of the choice of regulator. The calculation is analytic and straightforward. To the accuracy claimed, the only experimental inputs are simple low energy observables: the binding energy and pole residue of the deuteron, the nucleon iso-vector magnetic moment and the nucleon-nucleon scattering length in the ^{1}S$_0$ channel. Our result will therefore – to the accuracy claimed – be reproduced by any "realistic" potential model, and can hence serve as cross check. However, at higher orders beyond those presented here, there are contributions from certain four-nucleon-two-photon operators representing short-distance physics that might not be reproduced accurately in a model calculation. In conclusion, the polarisabilities are obtained in a model independent way by a fit to data, and no explanation as to their origin is attempted.

The letter is organised as follows: We start by outlining the framework of the calculation and the power counting needed to determine the theoretical accuracy. Then, the amplitude and cross section is presented. Finally, various fits of the polarisabilities to data

[1] In this letter, we express polarisability values in units of 10^{-4} fm^3.

are discussed. A more detailed presentation will be given in an upcoming article [14].

Our analysis is in the context of the few-nucleon EFT in which nucleons and photons are the only dynamical degrees of freedom [15]. This formulation can be viewed as a systematisation of Effective Range Theory to include interactions with gauge fields, and relativistic and short-distance effects. Contributions from pions and other, heavier degrees of freedom are included at low energy through multiple-nucleon-photon contact interactions in perturbation. Since one cannot apply this EFT at energies where cuts in the amplitude are probed due to pion propagation, meson exchange etc., the natural breakdown scale Λ is the pion mass $m_\pi \approx 140$ MeV. For details of the formalism, we refer to a recent review [16].

EFTs live from the fact that at low energies, a separation of scales exists: Like the binding momentum of the deuteron $\gamma = 45.7066$ MeV, the photon momentum $\vec{k}$ and energy $\omega = |\vec{k}|$ are much smaller than Λ. There is another "high-energy" scale, namely the iso-spin averaged nucleon mass $M_N = 938.92$ MeV. Thus, each physical low energy observable at a typical momentum scale $Q \sim \gamma$ is expanded systematically in powers of two small parameters: $\frac{Q}{\Lambda}$ and $\frac{Q}{M_N}$. For convenience, we formally identify $\Lambda/M_N \sim Q/\Lambda$, which is accidentally valid. Thus, relativistic corrections with a typical size $\gamma^2/M_N^2 \sim (Q/M_N)^2 = (Q/\Lambda)^2 \times (\Lambda/M_N)^2$ contribute at $\mathcal{O}((Q/\Lambda)^4)$, i.e. N^{4}LO, see Refs. [15, 17, 18].

The centre-of-mass photon energy ω and the conversion of relativistic photon energies to non-relativistic nucleon energies introduce new scales: ω and $\sqrt{\omega M_N}$. Therefore, it is convenient to separate the calculation into two different energy régimes [12]. In *régime I*, $\omega \lesssim \gamma^2/M_N$, and $\sqrt{M_N\omega} \sim \gamma \sim Q$. We concentrate on *régime II*, i.e. higher photon energies $\omega \sim \gamma \sim Q$, in which factors of $\sqrt{\omega M_N} \sim \Lambda$ are summed to all orders. In addition, we make some integral approximations that allow us to effortlessly move from one régime to another with one simple expression [12]. Details of the power counting, calculation and validity of the approximations will be provided in a future publication [14].

In the Weyl gauge $A_0 = 0$, the amplitude for Compton scattering can be written as

$$\mathrm{i}\mathcal{A} \;=\; \mathrm{i}\,\frac{e^2}{2M_N}\left[S\;\vec{\varepsilon}_d\cdot\vec{\varepsilon}_d^{\,\prime *} + V_i\;\epsilon_{ijk}\;\varepsilon_{d,j}\varepsilon_{d,k}^{\prime *} + T_{ij}\;\left(\varepsilon_{d,i}\varepsilon_{d,j}^{\prime *} + \varepsilon_{d,j}\varepsilon_{d,i}^{\prime *} - \frac{2}{3}\delta_{ij}\;\vec{\varepsilon}_d\cdot\vec{\varepsilon}_d^{\,\prime *}\right)\right] \quad , (1)$$

representing the scalar S, vector V and tensor T coupling of a photon with incoming (outgoing) polarisation $\vec{\varepsilon}_\gamma$ ($\vec{\varepsilon}_\gamma^{\,\prime}$) with a deuteron of incoming (outgoing) polarisation $\vec{\varepsilon}_d$ ($\vec{\varepsilon}_d^{\,\prime}$). $\frac{e^2}{4\pi} = \alpha = 1/137$. The power counting reveals that the vector and tensor amplitudes start contributing to the unpolarised cross section only at N^{4}LO. Hence the most dominant term is the scalar one. The centre-of-mass scalar amplitude S is conventionally written as

$$S \;=\; F(\omega,\theta)\;\vec{\varepsilon}_\gamma\cdot\vec{\varepsilon}_\gamma^{\,\prime *} + G(\omega,\theta)\;\left(\hat{\vec{k}}\times\vec{\varepsilon}_\gamma\right)\cdot\left(\hat{\vec{k}}'\times\vec{\varepsilon}_\gamma^{\,\prime *}\right) \quad , \qquad (2)$$

where F and G represent the scalar electric and magnetic amplitudes, and θ is the angle between the directions of the incoming and outgoing photon momenta, $\hat{\vec{k}}$ and $\hat{\vec{k}}'$. The familiar Thomson limit is reproduced by $F(\omega = 0) = 1$ and $G(\omega = 0) = 0$.

For F and G, an expansion in powers of Q/Λ exists, $F = F^{(0)} + F^{(1)} + \ldots$ etc., where the superscript denotes the contribution of order $(Q/\Lambda)^n$. We keep all N^{2}LO, i.e. $(Q/\Lambda)^2$,

corrections compared to LO, $\mathcal{O}((Q/\Lambda)^0)$. One such effect is the deuteron wave function renormalisation, introducing factors of $Z_d - 1$. $Z_d = 1.690(3)$ is the residue of the scattering amplitude at the deuteron pole and corresponds to the normalisation of the deuteron wave function at large wave length. $Z_d - 1$ is treated as $\mathcal{O}(Q/\Lambda)$, see Ref. [19] for details. Higher order corrections such as relativistic effects and ^{3}S$_1$-^{3}D$_1$ mixing are irrelevant for the present N^{2}LO calculation [15, 18]. Assuming that all contributions not taken into account are of natural size, we expect our result to be accurate to order $(Q/\Lambda)^3 \lesssim 0.03$. This error estimate lies at the heart of a model-independent, controlled approximation provided by EFT.

Now for details of the calculation, performed in the centre-of-mass frame. The contribution from the seagull diagram in Fig. 1 (a) scales as $\mathcal{O}((Q/\Lambda)^0)$, which constitutes a LO contribution in both energy régimes. We get

$$F_a^{(0)} = \frac{4\sqrt{2}\,\gamma}{\omega\sqrt{1-\cos\theta}}\ \arctan\left[\frac{\omega\sqrt{1-\cos\theta}}{2\sqrt{2}\,\gamma}\right] \quad ,$$
$$F_a^{(1)} = (Z_d - 1)F_a^{(0)} \quad , \quad F_a^{(2)} = 0 \quad , \quad G_a = 0 \quad . \tag{3}$$

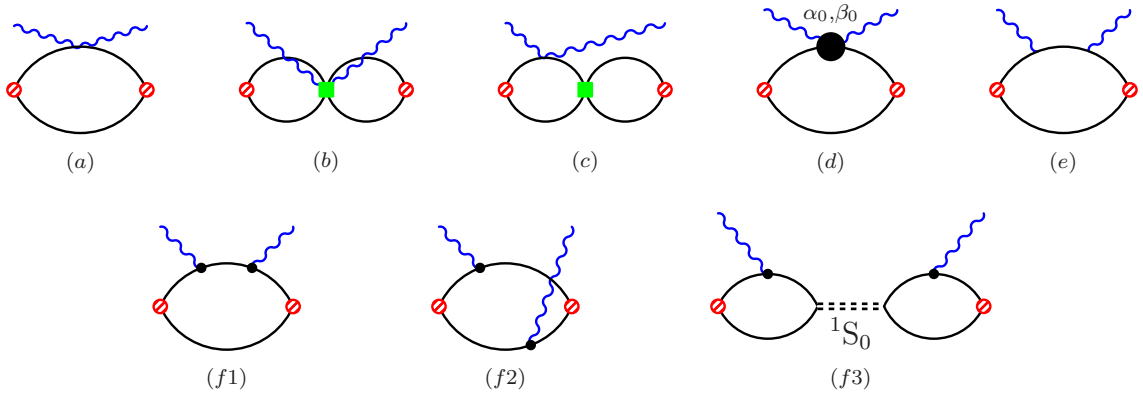

Figure 1: *Contributions to Compton scattering on the deuteron (represented by the circles) up to order $(Q/\Lambda)^2$. Solid lines: nucleons; wavy lines: photons; squares: four-nucleon contact interactions needed to reproduce the correct deuteron residue; large disk: interactions via nucleon polarisabilities; dots: magnetic (Fermi) interactions; dashed double line: ^{1}S$_0$ di-baryon. Graphs with a permutation of external lines or vertices are not displayed.*

Figures 1 (b) and (c) contribute at NLO in both régimes, and up to N^{2}LO

$$F_{b+c} = -(Z_d - 1) \quad , \quad G_{b+c} = 0 \quad . \tag{4}$$

Next, we consider the contributions from the iso-scalar, scalar electric and magnetic nucleon polarisabilities with Lagrangean $\mathcal{L}_{\rm pol} = 2\pi(\alpha_0\vec{E}^2 + \beta_0\vec{B}^2)N^\dagger N$, where $\alpha_0 := (\alpha^{(p)} + \alpha^{(n)})/2$ and $\beta_0 := (\beta^{(p)} + \beta^{(n)})/2$. The polarisability diagrams in Fig. 1 (d) contribute at different orders in the different energy régimes:

$$F_d = -\frac{2\alpha_0 M_N}{\alpha}\,\omega^2\,F_a \quad , \quad G_d = -\frac{2\beta_0 M_N}{\alpha}\,\omega^2\,F_a \tag{5}$$

The nucleon as point-like particle can only be polarised by its pion cloud, and at LO in χPT $\alpha_0, \beta_0 \sim \alpha/(8\pi f_\pi^2 m_\pi)$, i.e. numerically 2 (α_0, β_0) $M_N/\alpha \sim 1/\Lambda^2$ with $f_\pi = 131$ MeV $\approx m_\pi$ [5]. Thus, in régime I these diagrams are suppressed by $(Q/\Lambda)^6$. In contradistinction, they contribute at N^{2}LO, $(Q/\Lambda)^2$, in régime II.

The power counting for the diagrams in Fig. 1 (e) and (f) is slightly more involved because of factors of $\sqrt{\omega M_N}$ appearing in the propagators of the loop integrals from the conversion of relativistic photon energies to non-relativistic nucleon energies in the intermediate nucleon propagators. Some diagrams contribute at different orders in the different régimes. For example, in régime II ($\omega \sim \gamma$), Fig. 1 (e) is of order $\gamma/\sqrt{\omega M_N} \approx Q/\Lambda$ and contributes at NLO to F. Its contribution to the magnetic part G is suppressed by $(Q/\Lambda)^2$, i.e. N^{2}LO. But for small photon energies $\omega \lesssim \gamma^2/M_N$, Siegert's theorem requires this diagram to contribute as strongly as the seagull, Fig. 1 (a), because of gauge invariance. Indeed, the contribution to F from Fig. 1 is $\mathcal{O}((Q/\Lambda)^0)$, i.e. LO in régime I; to G it starts at N^{4}LO. We find for Fig. 1 (e) in régime II

$$\begin{aligned}
F_e^{(LO)} &= \frac{4\gamma\left[2\,\gamma^3 - (\gamma^2 - M_N\omega - \mathrm{i}\epsilon)^{3/2} - (\gamma^2 + M_N\omega)^{3/2}\right]}{3M_N^2\omega^2}\ , \\
F_e^{(NLO)} &= (Z_d - 1)F_e^{(LO)} - \cos\theta\, G_e^{(LO)}\ , \\
G_e^{(LO)} &= \frac{1}{15M^4\,\omega^2}\Big[8\gamma^6 + 20M\gamma^4\,\omega + 60M^2\gamma^2\,\omega^2 + 15M^3\,\omega^3 - 4\gamma\left(\gamma^2 - M\,\omega - \mathrm{i}\epsilon\right)^{5/2} - \\
&\qquad -\gamma\left(\gamma^2 + M\omega\right)^{1/2}\left(4\gamma^4 + 28M\gamma^2\,\omega + 39M^2\,\omega^2\right)\Big]\ , \qquad (6)
\end{aligned}$$

where the approximations made for analytic results agree with the exact answer to within 0.5%.

The nuclear magnetic moment contributions from Fig. 1 (f) are suppressed by factors of $(\kappa_1 Q/M_N)^2$ in both the energy régimes. Here, the square of the iso-vector nuclear magnetic moment in nuclear magnetons, $\kappa_1^2 = 5.536$, is anomalously large, given an expansion parameter of $Q/\Lambda \approx 0.3$. Numerically, Fig. 1 (f) is therefore expected to contribute at N^{2}LO, and we choose to include it. The iso-scalar magnetic moment $\kappa_0 \approx 0.4$ does not enter at N^{2}LO because it is of natural size. Fig. 1 (f3) contains intermediate two nucleon scattering through the ^{1}S$_0$ channel with a scattering length of $a^{(^1\mathrm{S}_0)} = -23.714$ fm $\sim 1/Q$. Analytic and exact results for the momentum integrals agree again to better than 0.5%.

$$\begin{aligned}
F_f^{(2)} &= 0\ , \\
G_f^{(2)} &= -\kappa_1^2\,\frac{4\gamma}{3M_N^2}\left(\gamma - \frac{1}{a^{(^1\mathrm{S}_0)}}\right)\left[\frac{\sqrt{\gamma^2 + M_N\omega} - \gamma}{\frac{1}{a^{(^1\mathrm{S}_0)}} - \sqrt{\gamma^2 + M\omega}} + \frac{\sqrt{\gamma^2 - M_N\omega - \mathrm{i}\epsilon} - \gamma}{\frac{1}{a^{(^1\mathrm{S}_0)}} - \sqrt{\gamma^2 - M\omega - \mathrm{i}\epsilon}}\right] \qquad (7)
\end{aligned}$$

To summarise, in régime II ($\omega \sim \gamma$) the electric and magnetic amplitudes to N^{2}LO are

$$\begin{aligned}
F^{(0)} &= F_a^{(0)}\ , \\
F^{(1)} &= F_a^{(1)} + F_{b+c}^{(1)} + F_e^{(LO)}\ , \\
F^{(2)} &= F_d^{(2)} + F_e^{(NLO)} + F_f^{(2)}\ , \\
G^{(0)} &= 0\ ,\ \ G^{(1)} = 0\ ,\ \ G^{(2)} = G_d^{(2)} + G_e^{(LO)} + G_f^{(2)}\ . \qquad (8)
\end{aligned}$$

As noted above, the scalar polarisability contributions to Compton scattering are suppressed by $(\omega/\Lambda)^2$. Up to N^{2}LO, Compton scattering is therefore sensitive to the nucleon polarisabilities α_0, β_0 only in régime II, where they enter as the only undetermined parameters, see (5) and (8). Thus photon energies $\omega \sim \gamma \sim 45$ MeV are most appropriate for extracting nucleon polarisabilities from a comparison of the differential cross section in the centre-of-mass frame

$$\frac{d\sigma}{d\Omega}\Big|_{\rm cm} = \frac{\alpha^2}{2\left(\omega+\sqrt{\omega^2+4M_N^2}\right)^2}\left[\left(|F|^2+|G|^2\right)(1+\cos^2\theta)+4{\rm Re}[FG^*]\cos\theta\right] , \quad (9)$$

expanded to N^{2}LO, with experimental data. Using the experimental values for the proton polarisabilities [4], we can then determine the neutron polarisabilities.

We now proceed to determine the polarisabilities from Compton scattering data at $\omega_{\rm Lab} = 49$ MeV [20]. If the LO χPT result $\alpha_0 = 12.4$, $\beta_0 = \frac{1}{10}\alpha_0$ [5] is taken at face value, one might assume that $\beta \approx 0$ at N^{2}LO. A χ^2 fit gives $\alpha_0 = 8.1 \pm 4.6$, with sizable 1σ errors[2]. Estimates of the NLO corrections in χPT seem to favour the electric and magnetic polarisabilities to have about the same size: Resonance saturation suggests $\alpha_0 = 12.0 \pm 2.5$ and $\beta_0 = 5.7 \pm 5.1$ [6], and treating the Δ as dynamical degree of freedom leads to $\alpha_0 = 16.4$, $\beta_0 = 9.1$ [7]. In the next step, we therefore fit both α_0 and β_0 as free parameters, resulting in $\alpha_0 = 8.4 \pm 3.0 \pm 1.7$ and $\beta_0 = 8.9 \pm 3.9 \pm 1.8$, again with large error bars from a two parameter fit to four data points. The first error comes from the fit, the second is the estimate of the theoretical uncertainties. However, the well measured Baldin sum rule constrains $\alpha_0 + \beta_0 = 14.05 \pm 0.67$ [21] which is also comfortably close to the sum of the polarisabilities from the naïve two-parameter fit. Utilising the sum rule, we find $\alpha_0 = 7.2 \pm 2.1$ and hence $\beta_0 = 6.9 \mp 2.1$ in a one parameter fit, with the best χ^2 of all the three procedures. Strictly speaking, the Baldin sum rule gives the sum of the polarisabilities only at zero photon energy, while the polarisabilities are extracted at $\omega = 47.7$ MeV. However, we assume that corrections are small [22]. Figure 2 compares the three fits to scattering data.

The calculation presented here is formally accurate to $\mathcal{O}((Q/\Lambda)^3)$, i.e. to within $\approx 3\%$. However, numerically the result might be slightly better as some contributions with sizes comparable to N^{3}LO are already included in (6) and (7) and the polarisabilities are by far the biggest N^{2}LO contributions. Figure 2 compares the strengths of the diagrams, confirming the power counting and demonstrating convergence. We can for example leave out the κ_1 contribution Fig. 1 (f) which acts like a large N^{3}LO correction, see Fig. 2. This enhances the electric polarisability using the Baldin sum rule to $\alpha_0 = 8.1 \pm 2.1$ and reduces β_0 accordingly. On the other hand, one might expect that wave function renormalisation effects on the polarisability diagrams are large because $Z_d - 1 = 0.69\ldots$ is large for a NLO effect. Still, the fit using the Baldin sum rule then induces only small changes in the polarisabilities, $\alpha_0 = 7.3 \pm 2.1$. We therefore estimate the theoretical uncertainty of our extraction at $\omega \approx 40$ MeV to be about 20% and refer to [14] for further discussion. The experimental uncertainty is at present higher than the theoretical error because of the comparatively high error bars in the only available low energy Compton scattering data.

[2]Unless otherwise stated, the errors are only from the fit and do not include the theoretical uncertainties.

Including the theoretical uncertainties in our calculation ($\approx 20\%$) and in the value of the Baldin sum rule, we find $\alpha_0 = 7.2 \pm 2.1 \pm 1.4 \pm 0.7$, $\beta_0 = 6.9 \mp 2.1 \mp 1.4 \mp 0.7$, where the first error comes from the fit, the second one is the theoretical uncertainty of our N^{2}LO calculation, and the third comes from applying the Baldin sum rule. For curiosity, we note that these values are also well consistent with the two Urbana data points at $\omega_{\rm Lab} = 69$ MeV [20] which give using the Baldin sum rule $\alpha_0 = 5.4 \pm 2.2$, $\beta_0 = 8.6 \mp 2.2$. We finally extract for the neutron polarisabilities $\alpha^{(n)} \approx (5;\, 2)$ and $\beta^{(n)} \approx (16;\, 12)$, where the first number in parentheses comes from the free fit, and the second from the fit using the Baldin sum rule. We quote no errors since they are large mainly due to the large experimental uncertainties. Higher values for $\alpha^{(n)}$ seem slightly favoured [14].

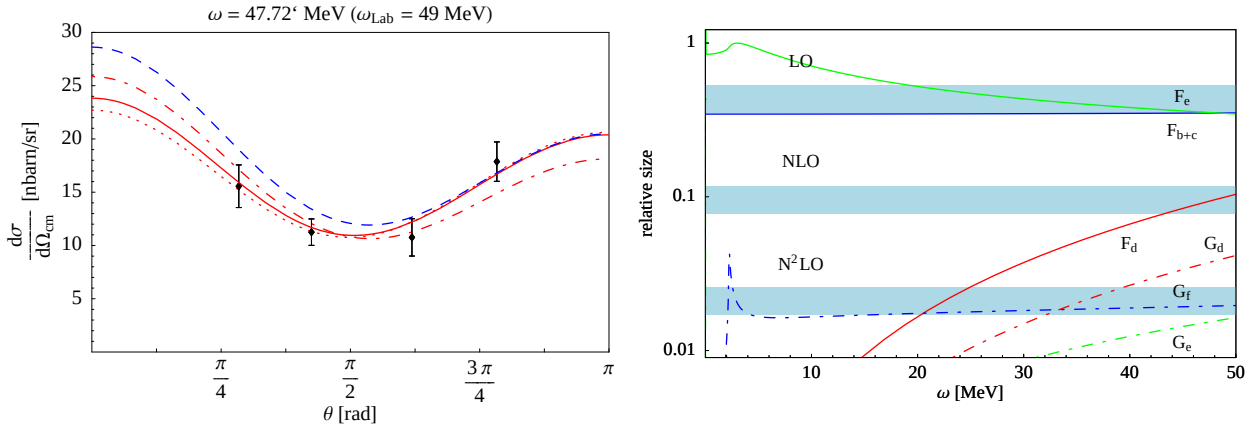

Figure 2: *Left: EFT result for the differential cross section fitted to data [20]. Dashed: $\alpha_0 = \beta_0 = 0$; dot-dashed: $\beta_0 = 0$; dotted: α_0 and β_0 fitted; solid: α_0 and β_0 constrained by the Baldin sum rule. Right: Sizes of the (angle averaged) contributions F_i and G_i, normalised to the LO contribution of the seagull term: $|F_i, G_i|/|F_a^{(0)}|$. The values assumed for the polarisabilities are* 12 *and* 5*. The grey bars are meant to guide the eye in determining the size of a contribution in the Q/Λ expansion.*

The gap between our extraction of the polarisabilities and the χPT results is well known, see e.g. [11]. It can be traced back to the fact that the Compton scattering data at large angles is systematically more and more enhanced over forward scattering as the photon energy is increased [20, 23]. This favours larger values of β_0.

Although the scarcity of data at low energies is a big hindrance, the comparison of the present calculation to experiment shows that it is quite appropriate to determine neutron scalar polarisabilities from low energy Compton scattering. Our approach uses EFT and hence it is model-independent and allows one to estimate the theoretical accuracy as $\sim 20\%$ for the polarisabilities, assuming higher order contributions are of natural size. Future higher precision experiments e.g. at TUNL in the energy régime $\omega \sim 25 - 50$ MeV would be most useful. As one can see from Fig. 2, at lower photon energies, the polarisability contributions become smaller than N^{2}LO, while higher energies introduce large theoretical errors since corrections going like ω/Λ are not suppressed sufficiently strong any more. The energy régime proposed is hence an interesting window of opportunity to determine nucleon

polarisabilities in a model-independent way without having to deal with pions as explicit degrees of freedom. Small angle scattering data constrains $\alpha_0 + \beta_0$ and hence can serve as a cross check to the Baldin sum rule, whereas backscattering data probes $\alpha_0 - \beta_0$ and hence is needed for a better determination of β_0. In a future publication [14], we will address details of the calculation as well as a more accurate estimate of N^{3}LO effects. The only undetermined operators entering at N^{3}LO are $(C_E\vec{E}^2 + C_M\vec{B}^2)(N^T P_i N)^\dagger(N^T P_i N)$ with projections P_i onto the $^3S_1$ channel. These operators contribute to residual electric and magnetic deuteron polarisabilities, i.e. to those not generated by polarisation of the two nucleons against each other or by polarising the nucleons themselves.

Acknowledgements

We are much indebted to discussions with the EFT group at the Institute for Nuclear Theory and the Physics Department at the University of Washington in Seattle, particularly with M. J. Savage, as well as with Th. Hemmert and N. Kaiser. H.W.G. wants to emphasise especially the hospitality of the INT during the Summer 2000 Workshop on "Effective Field Theories and Effective Interactions", and its financial support. The participants of the workshop created a highly stimulating atmosphere. We also acknowledge support in part by the Bundesministerium für Bildung und Forschung (H.W.G.), the DFG Sachbeihilfe GR 1887/1-1 (H.W.G.), the US Department of Energy grant DE-FG03-97ER41014 (G.R.) and the Natural Sciences and Engineering Research Council of Canada (G.R.).
